SUMMARY

Models predicting the nutrient partitioning and animal performance have been developed for decades. Nowadays, growth models are used in practical animal nutrition, and they have particular importance in precision livestock farming. The aim of the present study was to introduce a broiler model and to provide examples on model application. The model predicts protein and fat deposition as well as the body weight of an individual broiler chicken from digestible nutrient intake over time. Feed intake (FI) and the digestible nutrient content of the feed are inputs as well as some animal factors like: initial BW, feed intake at 1 and 2 kg of BW, precocity and mean protein deposition. The protein and energy metabolism is represented as in the classical nutrient partitioning models. The protein deposition (PD) is driven by digestible amino acid supply and is under “genetic control”, the so called potential PD limits the actual PD if protein is oversupplied.

The authors discuss how the model can be used to simulate the animal response upon different scenarios. Examples are given to show that the diet might be limiting if some animal trait is changed. Applicability of the model has shown through running the model by using different feed strategies (three- vs five-phase-feeding) and variations with animal factors. In conclusion, growth models are useful tools to support decision making for defining the most suitable feeds used in a broiler farm. The model presented in this paper shows a high sensibility and flexibility to test different scenarios. By challenging the model with different inputs the animal response in terms of changes in body weight and feed conversion can be understood more by studying the shift in deposition of chemical constituents. The examples provided in the present paper shows the benefit of using mathematical models and their applicability in precision nutrition. It can be concluded that the growth model helps to apply “from desired feed to desired food” concept.

Keywords: broiler, growth model, protein and fat deposition, feed efficiency.

INTRODUCTION

In early ‘60s the world produced less than 10 million tonnes of poultry meat and by 2013 that was more than 96 million tonnes (FAOSTAT 2017). This increment in production volume is attributed not only to a larger number of slaughtered broilers but a higher body weight at slaughter. On the other hand evolutionally meat type chickens reach market in younger age due to artificial selection for commercial objectives, and the number of days, total feed and in turn energy required raising a broiler to slaughter weight have decreased dramatically. Genetic improvement in poultry is faster than in other species because poultry breeders have advantages of large population size, short generation interval and considerable genetic variation available to them (McKay, 2009). Broiler chicken’s growth rate increased by over 400 % between the years of 1950 and 2005 (Zuidhof et al., 2014). Due to increased growth rate, both the energy intake per day and the metabolic heat production rate have increased, whilst the efficiency of utilising energy for growth has improved (Tallentire et al., 2016). The better energy efficiency comes from improved metabolic efficiency in modern breeds selected on high-quality feed. In result, broilers reach slaughter weight more quickly and therefore need to allocate less energy overall to basal metabolic processes.

Chemical and physical body composition systematically changes during the growth and these changes became into the scientific focus more than ninety years ago (Mitchel et al., 1926). The growth of the body is the sum of changes in chemical constituents. Chemical components follow a certain pattern as a function of age and based on that there has been number of attempts to predict the growth and body composition of chicken of various genotypes (Hurwitz et al., 1978; Emmans, 1981, 1995; Hancock et al., 1995; Hruby et al., 1996; Horn et al., 1998; Sütő et al., 1998; Gous et al., 1999; Markato et al., 2008; Sakomura et al., 2011; Henn et al., 2014; Silva et al., 2014).

As a consequence of the genetic selection the nutrient requirement continuously changes in broilers. Nutrient requirements of broiler breeds in the 1950’s have been distinctly lower than nowadays. First recommendation for broilers nutrients supply have been set up by NRC in the 1960’s and have been adapted several times, the 1994 edition of NRC being the latest one (NRC, 194). Broiler chickens of any strains have been selected for rapid weight gain and efficient utilization of feed (Havenstein et al., 2003a,b). The higher growth rate is attributed to the higher protein deposition rate thus the protein and more particularly the essential amino acid requirements increased. This higher demand for amino acids is fulfilled by providing synthetic amino acid supplementation in practical broiler feeds (Grashorn, 2017).

There are nutritional tables declaring the energy, amino acid as well as mineral and vitamin requirement of broilers. Most of them, however, do not consider the differences in nutrient requirement of different genetic potential

strains. Those recommendations presume an intensively grown broiler with an “ideal” feed intake. In this term, those static recommendations are rather just approximate target values for the feed formulation. Each breeder has its own guideline for the nutrient requirement of the strain, but those recommendations are often overestimated the real requirements to simply be on the safe side. It has to be noted, however, that it is difficult to establish a single set of requirements even for a certain strain of broiler because nutrient requirements may vary according to the criterion of adequacy. In the instance of essential amino acids, greater dietary concentrations may be required to optimize efficiency of feed utilization than would be needed to maximize weight gain (NRC, 1994). There is also evidence that the dietary requirement for lysine to maximize yields of breast meat of broilers is greater than that needed to maximize weight gain (Acar et al., 1991) and differences exist among strains of broilers with respect to need for more lysine (Bilgili et al., 1992).

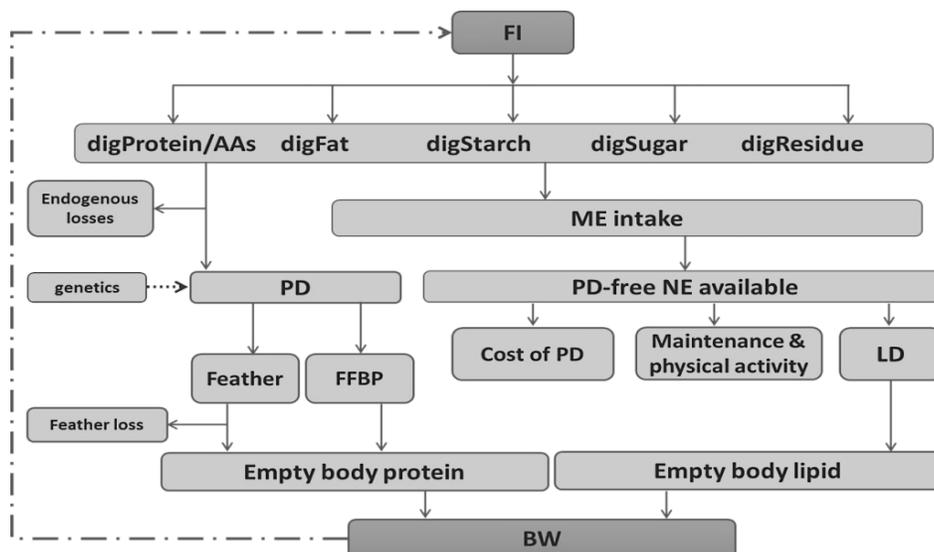

There is a general agreement that the nutrient requirement of the animals can be fulfilled more precisely if phase feeding is applied. The recommendations, however, for the time length of different phases are different. Also, it has been confirmed that the more phases are used, the more efficient is the production in terms of using less resources while excreting lower amount of nutrients. Therefore, static table values allow a less precise diet formulation and therefore they are not suitable for precision nutrition. In sustainability and profitability terms balancing dietary nutrients for actual feed intake is the prerequisite to support maintenance and growth precisely. This needs definitely a dynamic system approach. By their nature dynamic growth models offer that approach and thus they can be used as a tool to define the optimal feed at any time point or interval of growth phase. By mathematical models the nutrient requirement can be estimated precisely at different circumstances and the broiler production can be optimised, thus models support a more reliable decision making in practical farms.

The aim of the present paper is to introduce a broiler model and to provide examples on model application. The authors discuss how the model can be used to simulate the animal response upon different scenarios.

MODEL DESCRIPTION

The model predicts protein and fat deposition as well as the body weight of an individual broiler chicken from digestible nutrient intake over time (Dukhta et al., 2017). The model is therefore deterministic and dynamic, and it is considered as a mechanistic model even if some empirical equations are included. The protein and energy metabolism is represented as in the classical nutrient partitioning models (Emmans, 1981; de Lange, 1995, van Milgen et al., 2008). The flowchart on Figure 1 shows the nutrient flows of the metabolic model. Feed intake (FI) and the digestible nutrient content of the feed are inputs as well as some animal factors like: initial BW, feed intake at 1 and 2 kg of BW, precocity (indicating the maturity rate), mean protein deposition. The daily protein deposition (PD) derives from the digestible amino acid supply that remains after subtracting the obligatory urinary and faecal endogenous losses. The protein deposition is under “genetic control”, the so called potential PD limits the actual PD if protein is oversupplied.

Figure 1: Nutrient flow of the metabolic model for broiler chicken

Dukhta et al., 2017

Historically, Gompertz equation has been used to describe the growth of an animal in terms of BW as a function of time. In the broiler model the protein mass at non-limiting condition (considered as its genetic potential) is described by a modified Gompertz function as suggested by van Milgen et al. (2008). The modified Gompertz equation is used to obtain the potential daily PD. By using that approach, protein deposition has a limitation by genetic potential, and became driven by state and not by age, meaning that compensatory PD can occur.

In fact, the sophisticated Gompertz equation for body protein mass is as follows:

$$P_t = P_m \cdot \exp[-\exp((\ln(-\ln(P_i/P_m)) - (B \cdot t)))]$$

where:

$$P_m = prot_final \cdot (prot_final / prot_init)^{(Bf / (1-Bf))}$$

$$duration = age_final - age_init$$

$$Bf = \exp(-precocity \cdot duration)$$

$$Prot_final = duration \cdot (meanPD / 1000) + prot_init$$

$$\text{and Potential PD} = precocity \cdot prot_init \cdot \ln(P_m / prot_init)$$

where: P_t - protein mass at time t ; P_m - protein mass at maturity; $prot_final$ - protein weight at the end of simulation; $prot_init$ - initial protein weight at hatch; B , $precocity$ - maturity rate; age_final - age when maximum growth rate is achieved; age_init - hatching day (0 day); Bf - fractional rate of growth, $mean PD$ - the mean protein deposition in the simulated period. MeanPD value closely related to average daily gain, interacting with precocity gives a specific meaning to growth function and determines the early or late maturing of the animal.

The daily protein deposition in the model is divided between feather protein development and feather free empty body protein deposition. The first one is determined by a classical Gompertz function described by Emmans (1981) and considered as an obligatory flow. The feather loss is also taken into account in the model as a part of maintenance needs.

Digestible nutrients provide the metabolizable energy for the bird and the efficiency of energy yielded from different nutrients are taken into account. Factors for energy conversion of digestible nutrients to metabolizable and net energy are presented in *Table 1*. The values were determined by Carré et al. (2014). In the model the energy is used for maintenance and it supports the energy needed for the actual PD, protein turnover as well as physical activity, and the rest is converted to body lipid.

The amount of water and ash in the body is assumed to be proportional with the body protein mass. Ash in empty body weight is presumed to be 20% of the empty body protein, while the water mass is described by allometric function of empty body protein.

Table 1.

Energy conversion factors used in the broiler model (kJ/g, according to Carré et al., 2014)

	Coef ME	Coef AMEn	Coef NE
CrudeFat	38.38	37.77	32.43
CrudeProt	20.60	18.36	14.32
Starch	17.00	16.67	13.28
Sugars	13.02	12.52	7.932
Residue	9.93	9.30	12.71

As it is shown in *Figure 1*, the feed intake is driven by body weight. The equation that is used for the estimation of the daily feed intake is based on the premise that the birds eat for their energy requirement. The so called Gamma-function is a transposed exponential equation that shows the net energy intake (NEI) capacity of the bird as a function of maintenance. The approach was adapted and the equation was re-parametrised from the pig model InraPorc (van Milgen et al., 2008).

$$NEI (MJ/d) = (a \cdot b \cdot BW \cdot \exp(-b \cdot BW) + 1) \cdot c \cdot BW^d$$

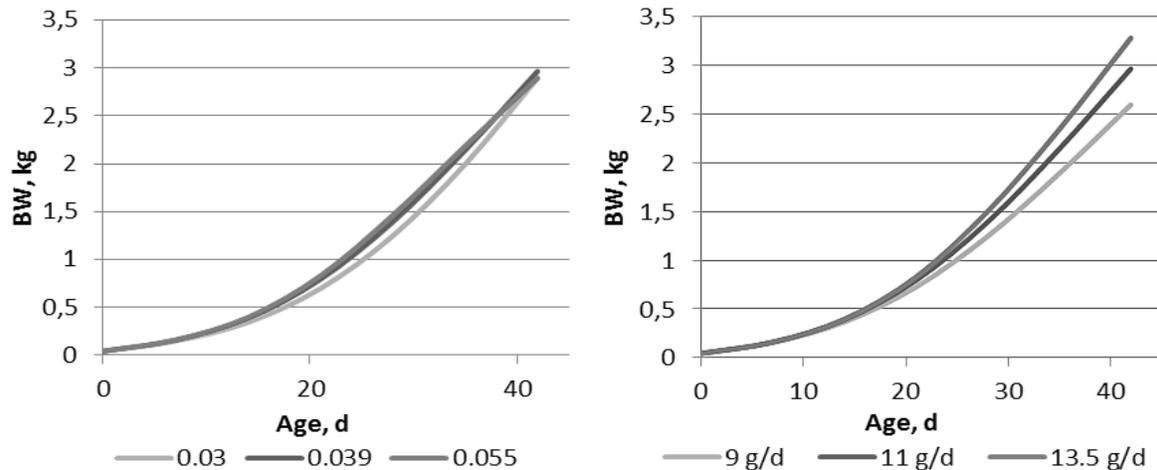

where: a and b are coefficients calculated from FI at 1 and 2 kg of BW; $c = 0.8$ - coefficient related to maintenance (Carré et al., 2014); $d = 0.7$ - power for metabolic body weight (Noble et al., 2015).

It has been proven that the model predicts the ideal trajectory of feed intake with high precision in optimal environmental and health conditions (Dukhta et al., 2017).

As it was mentioned the model has feed related parameters and certain animal traits as inputs. The animal is characterised by initial body weight, precocity as an indicator of the shape of protein growth, as well as by mean PD. This parameterisation is convenient for model users as the parameters have a biological and practical meaning (*Figure 2*). The higher precocity value results in an early-maturing animal, and the low precocity reflects to a late-maturing animal. By changing precocity value, the mature body weight is not changing seriously. The meanPD certainly determines the maximum protein deposition and, thus, this is the main driving force for the potential body weight at any time step. There is considerable difference in the shape of growth between males and females. Males

are heavier and leaner than females, and the difference between sexes appears from approximately 3 weeks of age (Horn et al., 1998). Literature data for precocity of protein deposition in broilers vary between 0.038 to 0.056 among different strains and sexes, while the mean PD for a 42 day growing appear between 9 and 14 g/day (Hancock et al., 1995; Gous et al., 1999; Marcato et al., 2008; Henn et al., 2014; Silva et al., 2014; Gonçalves and Sakomura, 2017).

Figure 2: Predicted body weight (BW) at fixed mean PD (11 g/d) and different precocity parameters (left) and at fixed precocity (0.040) and different mean PD (right)

APPLICATION OF THE BROILER MODEL

The model is available to test different scenarios and therefore it helps to make decision according to the simulation results. In the following case studies the model is challenged with different inputs studying the effect of individual animal traits such as precocity and mean PD (case study 1) as well as with different feeding strategies (case study 2). In case study 3 the same diets and feeding regime is used and the performance (BW and chemical body composition) of two different characteristics animals are simulated.

In simulations the model was run with diets as shown in *Table 2* and the initial conditions of animal traits were the same in both simulations: initial BW = 44 g; FI at 1 kg BW – 1.2 and at 2 kg BW – 1.9 kg; precocity: 0.040; meanPD = 11 g/d; duration is 42 days.

Table 2.

Nutritional composition of the diets in model simulations

	3 phases feeding			5 phases feeding				
	0-14 d	15-28 d	29-42 d	0-10 d	11-20 d	21-28 d	29-35 d	36-42 d
AMEn	13.00	13.00	13.00	13.00	12.99	12.84	12.56	12.36
CP	24	22	19	24	22	21	20	19
dig Lys	1.56	1.33	1.14	1.56	1.33	1.14	1.18	1.14
dig Met	0.55	0.47	0.40	0.55	0.47	0.40	0.42	0.40
dig Thr	0.90	0.80	0.71	0.90	0.80	0.75	0.72	0.71

In case study 1 dietary inputs of nutrient content of three-phase reference diets was taken from literature (Gonçalves and Sakomura, 2017). It has been discussed that precocity reflects to the dynamics of protein deposition. The first simulation shows the broiler response in terms of protein and lipid deposition if nothing else but the precocity is different (*Figure 3*). The output of the simulation stresses that by changing the precocity value the diet can be limiting for the birds. In case of a higher precocity, when the animal is early-maturing, and thus it has more intensive growth potential at the early ages, the starter diet as used in the present simulation is not sufficient to supply enough amino acid for a high genetic potential. The simulated results suggest that either the feed intake or rather the amino acid supply should be increased by supplementing the diet with amino acids or enhance the digestibility of the protein. However, the model also shows that the better amino acid supply is applicable only in the first 18 days but

not later. The figure emphasizes that the fat deposition and consequently the fat content of the body is higher at the slaughter age if the bird is early-maturing. However, due to the fact that the fat deposition is a “sink of the energy”, by reducing the dietary energy content of the finisher feed the body fatness can be reduced.

Figure 3: Predicted daily protein and lipid deposition with three-phase-feeding when meanPD is set as 11 g/d and precocity is 0.040 and 0.050 shown on the left and right sides, respectively

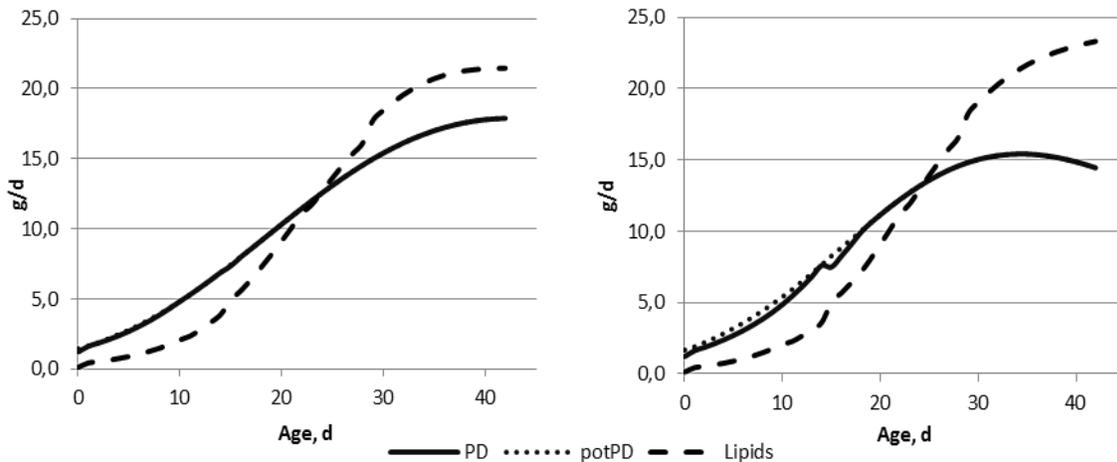

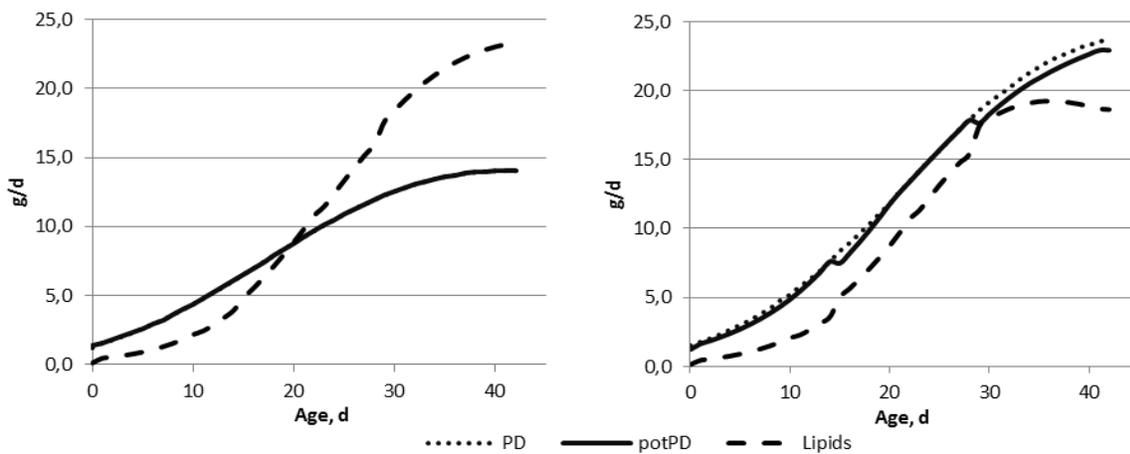

Figure 4 shows the model output if the precocity value is fixed (0.04) and the meanPD is changed from 9 to 14 g/d. The feeding regime is the same as in the earlier simulation (three-phase-feeding). Based on comparison of the scenarios it can be concluded that the diet was limiting for the birds having a higher meanPD throughout the growing and finishing periods. It is also clearly seen that the protein (and amino acids) was oversupplied in case of low meanPD birds. The actual PD that is allowed by the diet is much higher in the right figure, indicating that the genetic potential limited the protein deposition in the left figure. The low meanPD attributed with a higher fat deposition coming from unused dietary protein. The protein deposition requires considerable amount of energy and thus in high genetic potential birds (higher mean PD) the energy remained for lipid deposition was much less compared to the low genetic potential counter pair.

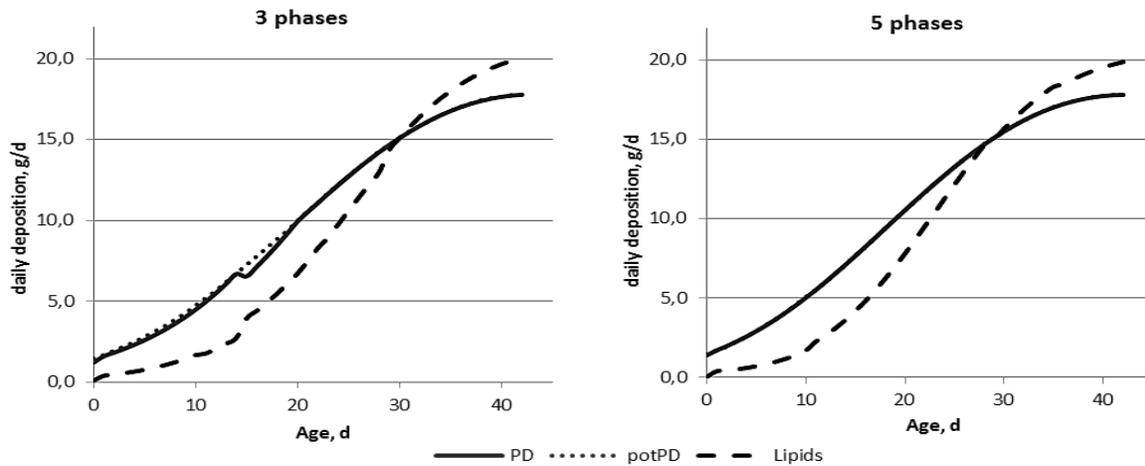

Figure 4: Predicted daily protein and lipid deposition with three-phase-feeding when precocity parameter is fixed (0.040) and meanPD is different being 9 and 14 g/d on the left and right sides, respectively

In case study 2 different feeding regimes were compared. The model is challenged with a classical 3-phase-and with a 5-phase-feeding regime (Table 2). The animal traits were kept the same in both simulations as defined above in this paper. The results of the simulations are shown in Figure 5 and 6. It can be concluded from the PD curves,

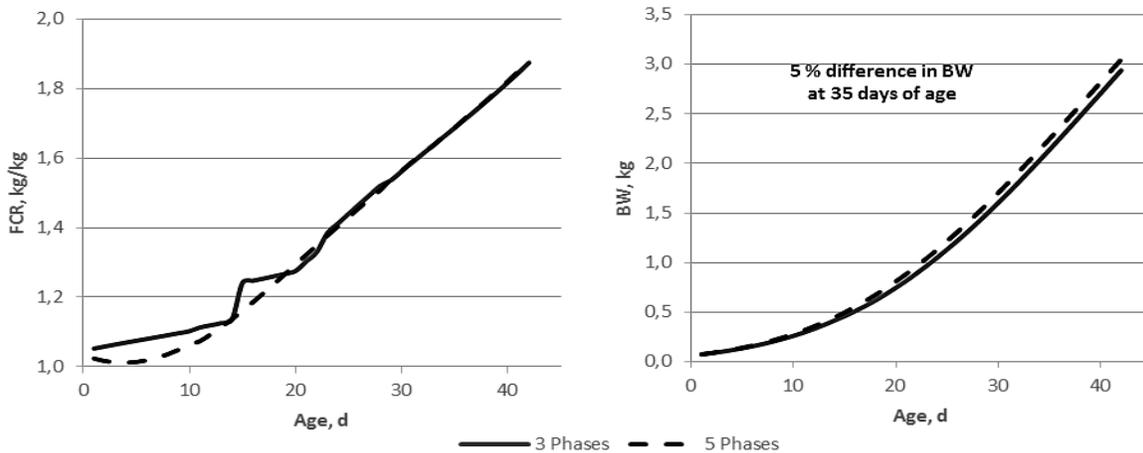

that PD is limited by the diet in some periods if three-phase-feeding was applied, and therefore, fat deposition became a more 'noisy' curve. However, there is no major difference in protein and lipid deposition rates. The more phases are usually attributed to the better feed conversion, if not just the number of periods are increased, but the nutrient supply is also adjusted.

Figure 5: Predicted daily protein and lipid deposition with three-phase-feeding (left) and five-phase-feeding (right) when precocity parameter is fixed (0.040) and meanPD is 11 g/d

That can be confirmed in our simulation too. *Figure 6* (left graphs) shows that feed was more efficiently used if 5 phases were applied. The feed conversion ratio (feed/gain) was higher at the first 20 days if 3-phase-feeding was used. A slight difference in PD at beginning of first two phases (see *Figure 5*) caused some shift in feed conversion rate. Feed conversion is the efficiency of the diet and it reflects on the economic cost of the production. Any difference in slaughter weight has also impact on the profitability of the meat production. The graphs of *Figure 6* (right) show that at 35 day of age there is 5 % (~110 g) difference in BW. With more feeding phases the nutrient requirement was more precisely supplied, and it resulted in higher body weight at 5-phase-feeding simulation.

Figure 6: Comparison of predicted FCR and BW with different phase feeding

As it was shown the higher is the body PD, the higher is the BW gain and the better is the feed conversion ratio. Difference in BW is usually attributed to the difference in deposition of chemical constituents. In case study 3 two different growth characteristics birds' response is simulated. Five-phases-feeding regime defined in *Table 2* and two sets of initial input parameters were used: initial BW (44 g) and duration (42 days) were the same, when FI at 1 and at 2kg of BW were 1.2 – 1.8 and 1.3 – 2 kg; precocity 0.040 and 0.055; meanPD 11 and 9 g/d, respectively for the two simulations. The two different genetic potential animals may represent the two sexes. Males have lower

precocity and higher meanPD than females.

Figure 7 shows the output of the simulation on BW and protein and lipid mass. BW on the left graph is almost 3 kg at 42 days of age, empty body protein mass is more than 0.5 kg and empty body lipid is less than 0.4 kg. Those values are realistic for a modern male hybrid, such as our simulation for a female: 2.7 kg BW at 42 days of age, 0.45 kg of protein and almost 0.5 kg of empty body fat (Gonçalves and Sakomura, 2017). The difference in chemical body composition of males and females is also confirmed by the simulation, results of simulations on Figure 7 show that bird on the left is much leaner, comparing to the right one.

Figure 7: Predicted BW, cumulative body protein and body lipid with five-phases-feeding and two sets of parameters

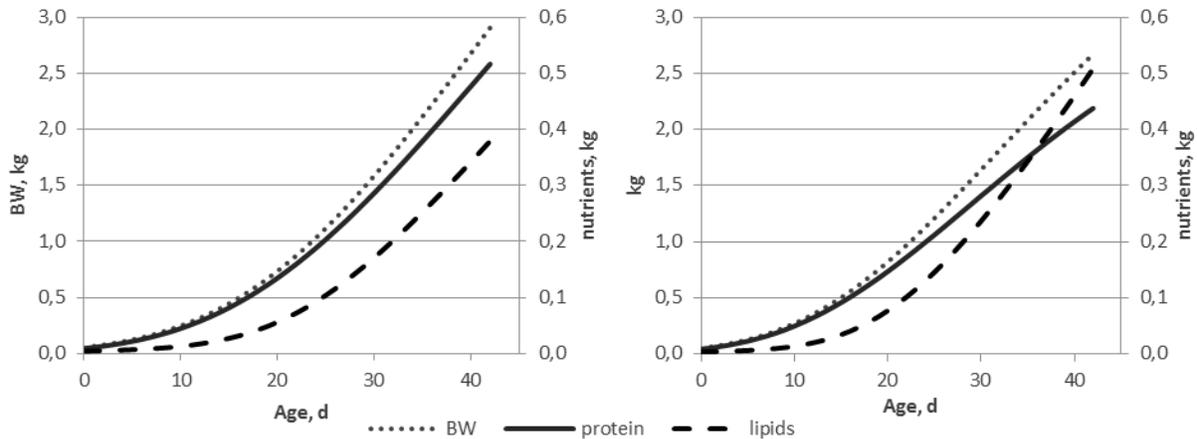

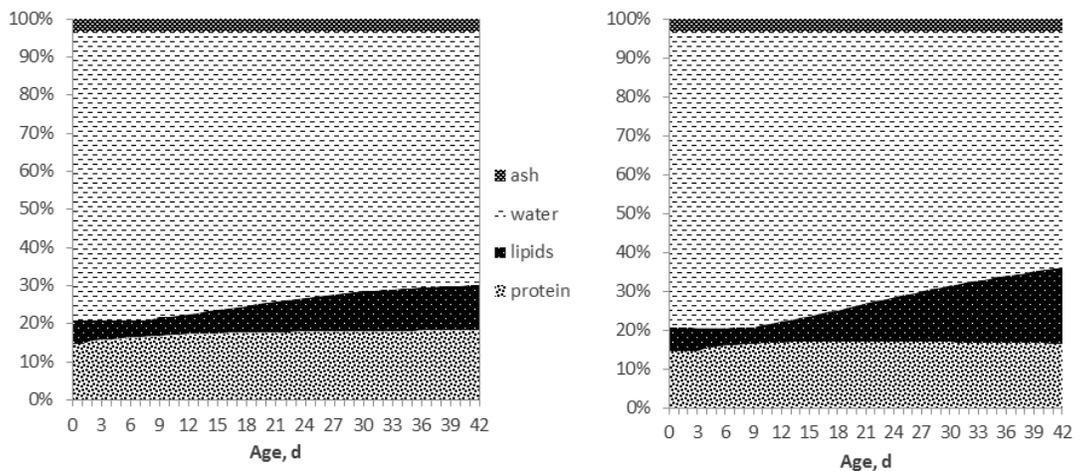

Figure 8: Predicted body compositions simulated with five-phases-feeding and two sets of parameters

CONCLUSION

Growth models are useful tools to support decision making for defining the most suitable feeds used in livestock farms. The model presented in this paper shows a high sensibility and flexibility to test different scenarios. By challenging the model with different inputs the animal response in terms of changes in body weight and feed conversion can be understood more by studying the shift in deposition of chemical constituents. The examples provided in the present paper shows the benefit of using mathematical models and their applicability in precision nutrition. It can be concluded that the growth model helps to apply “from desired feed to desired food” concept.
